1 Introduction

from the last lab The purpose of this lab is to learn and test with the Assembly language in a hands on environment in order to solidify the concepts learned in class and to improve our skill in the language. In addition, we will be learning how to handle the Netburner ColdFire boards directly, manipulating the contents of their memory and data structures. Finally, we are going to learn how to work inside the Eclipse IDE environment and how to properly use the powerful tools that come alongside it.

The code will be developed for the Netburner ColdFire Platform, which has some parameters that should be kept in mind throughout testing. There are multiple Data and Address registers, and the memory is indexed by hexadecimal codes. The data and the stored locations can each be modified directly, values can be compared and the code can branch into different sections depending on the values of the CCR (Condition Code Register) bits, which store information about the outcome from the last comparison or valid operation, such as if a value is negative or zero. These will be used to execute code conditionally.

The lab will be split into two sections, each with a different goal but with similar implementations. For one part we will be taking in an ASCII value and if the character it represents is a character included in the symbols for hexadecimal numbers then that hexadecimal value is output, otherwise it returns an error. For the second part an ASCII value is taken in, and if the character it represents is a letter in the English language (A-Z) then the ASCII code for the character in the opposite case is output. Thus, valid uppercase English letters are converted to their lowercase equivalents in ASCII and vice versa.

These experiments will introduce implementing high level programming practices of loops, if - then - else statements, using the Assembly language. More specifically, this will introduce the movement of memory and data to and from different parts of the Netburner chip, using techniques such as referencing memory addresses and copying data to local data registers. The debugger tools of the IDE will be used to closely examine this movement and to analyze all changes to the data in order to solve issues in development as well as to test the code. This is all building off the concepts explored in Lab 0.

The computing science practice of Pair Programming was also introduced, where two people develop and test code in tandem. The partners are divided into the Driver and the Navigator. In this structure the Driver is the one responsible for the physical typing of the code into the computer, and the Navigator reviews this code and clarifies the meaning of each passage in order to find bugs faster and to improve efficiency in testing. The two partners should communicate constantly and switch in order to maximize the efficiency of this working model. This will not only decrease time needed for development but it will also improve the quality of code from each partner.

2 Design

2.1 Part A

For the first part of the lab, we wrote code to add the contents of two arrays stored at different memory locations, and the result is stored at another specified memory location. This is done using three different addressing modes. In the first part, we use Register Indirect With Offset, in the second part, we use Indexed Register Indirect, and in the third part, we use Postincrement Register Indirect. All information is stored as a long word (32 bits). The operational code is provided

at memory location 0x2300000, which contains the information for where to access the arrays in memory and where to store the sum. For example, the number stored at 0x2300000 contains the size of the arrays. The operational code is stored as follows:

1. 0x2300000 - Size of arrays

2. 0x2300004 - Address of first array

3. 0x2300008 - Address of second array

4. 0x230000C - Address of where to store the sum with Register Indirect With Offset

5. 0x2300010 - Address of where to store the sum with Indexed Register Indirect

6. 0x2300014 - Address of where to store the sum with Postincrement Register Indirect

The *SetZeros.s* and the *DataStorage.s* files, which were provided, were used to initialize memory contents.

2.1.1 Part 1: Register Indirect With Offset

We chose address register a1 to store the contents at 0x230000C, which is where the address to output the sum is located. This was done by loading the effective address into a1, and moving the contents of the memory location stored at a1 into a1 itself. In a similar fashion, address register a2 was chosen to store the contents at 0x2300004, which stores the starting address of the first array to be added. Similarly, address register a3 was chosen to store the location of where the second array to be added starts, and that memory address is stored at 0x2300008. To add the first two numbers in the arrays, the contents of the memory location pointed to by a2 were moved into data register d3, and the contents of the memory location pointed to by a3 were added to d3. The result in d3 was then stored at the memory location pointed to by a1. Next, these three lines of code were copy-pasted and modified to add offsets to the memory locations. So, to add the next two numbers in each array, the contents of the memory location (4,%a2) was moved to d3, the contents of the memory location (4,%a3) was added to d3, and the result in d3 was moved to the memory location (4,%a1). The same method was applied to add the third numbers in the arrays, but this time with an offset of 8.

2.1.2 Part 2: Indexed Register Indirect

The loading of the memory addresses in part 2 was done very similarly to part 1. Address registers a2 and a3 still contain the memory locations of where the first and second array begin. However, the contents at memory location 0x2300010 was moved to a1, which is where the result is stored for this part. Data register d1 was chosen to store the amount by which we want to offset, and d2 was chosen to be our counter variable for a loop. Additionally, both these data registers were cleared. Inside the loop, the contents of the memory location stored by a2 were moved to d3, just like in part 1. Except this time, it was offset by the number in d1. So, on the first loop iteration, it would be displaced by 0. Similarly, the contents of the memory location pointed to by a3, displaced by the value at d1, is added to d3. The result stored in d3 is then moved to the memory location a1, also displaced by the number stored in d1. At the end of the loop, we increment the offset d1 by 4, and the counter is incrmented by 1. Then, we compare our counter to the size of the arrays, which

is a value stored at 0x2300000, and if our counter is less than the size of the array, we continue the loop.

2.1.3   Part 3: Postincrement Register Indirect

Loading of the memory addresses in part 3 was also very similar to parts 1 and 2. Address registers a2 and a3 are unchanged, but the contents at memory location 0x2300014 was moved to address register a1, which is where the result is stored in this part. We chose data register d2 to be our counter variable, which was initially cleared with the value of 0. Just like for part 2, we have a loop, but this time there are no offsets. Instead, we move the contents of the memory location pointed to by a2 to d3, and postincrement a2. Similarly, the contents fo the memory location pointed to by a3 is moved to d3, and a3 is post incremented. At the end of the loop, the counter is incremented by 1, and if it is less than the size of the arrays (stored at 0x2300000), the loop continues.

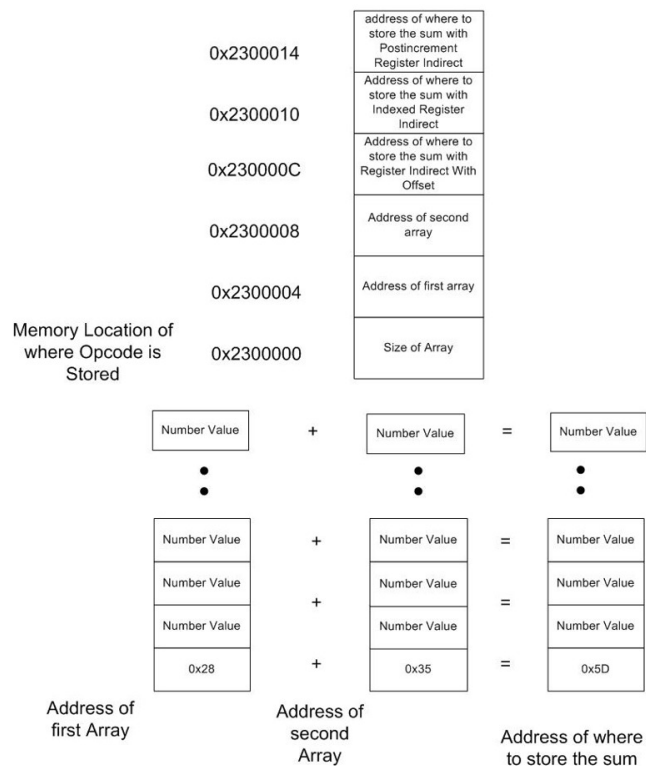

Figure 1: An illustration of how the data is organized in part A

2.2   Part B

from the last lab The design for Part B was very similar to Part A. The address register a1 still initially points to 0x2300000, but this time, a2 now points to 0x2320000, which is where the

converted data is stored.The same data register d2 was used to temporarily store the input and process the data. Just like in Part A, the *SetZeros.s* and the *DataStorage.s* files were used to initialize memory contents as well.

Once again, we had a loop branch that initially loads input data from the location pointed to by a1 into data register d2, and the ASCII 'Enter' code still terminates the program, as before. In Part B, valid inputs are the ASCII characters A-Z and a-z (0x41-0x5A and 0x61-0x7A). Error handling was also similar to Part A, where the value 0xFFFFFFFF was stored at the memory location pointed to by a2. We had two branches to handle the two ranges of accepted characters.

For example, if an input character was in the range a-z, a difference was taken relative to the ASCII character 'a', and added to the ASCII character 'A'. The converted value is then stored at the memory location pointed to by a2, and the addresses stored in a1 and a2 are incremented by 4 before the loop starts over. The flowchart diagram can be found in the Appendix.

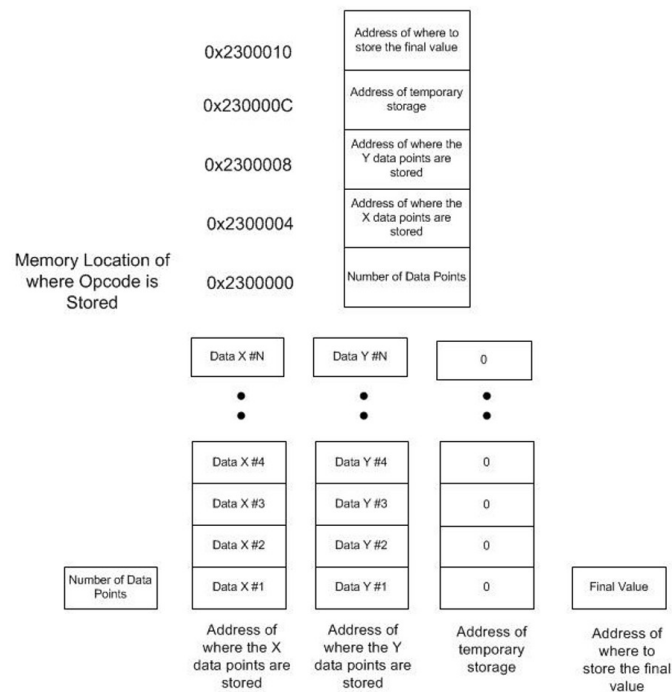

Figure 2: An illustration of how the data is organized in part B

3 Testing

3.1 Part A

from the last lab Initially, we visually tested our code by using the debugger in Eclipse IDE. While stepping through the code, we would check the values at relevant memory locations, and the data and address registers. When the bugs were ironed out, we went on to the next phase of

testing. Our code was tested using the provided *Lab1Test.s* file. More specifically, this program was moved into the project folder, downloaded to the ColdFire microcontroller, and the MTTTY serial monitor was loaded to monitor the expected output. Our code was further tested by replacing the 'DataStorage.s' file with the other variants provided named: *DataStorage1.s*, *DataStorage2.s*, and *DataStorage3.s*. Finally, our program, which produced the correct output, was verified by a lab TA.

Figure 3: MTTTY output when testing our Part A solution

3.2 Part B

from the last lab The procedure for testing our code for part B was very similar to the process described above in Part A. We visually inspected our code in the Eclipse IDE, used the Eclipse debugger to step through our code, and monitor relevant memory addresses and registers. When we were confident that we had a working solution, we used the provided files *Lab1Test.s*, and the *DataStorage*.s* files to verify our solution by downloading the program to the ColdFire microcontroller, and monitoring the output in MTTTY. Finally, our solution was verified by a lab TA.

Nunc quis urna dictum turpis accumsan semper.

7

5 Conclusion

from the last lab we encountered difficulties in part 1 because we accicdentally ended the program early This lab demonstrated how to perform operations and modify data while moving it around using the Assembly language for the ColdFire architechture. In addition, the lab improved our understanding of the debugger software, a very powerful tool in the development of this kind of code. The main issue we found was related to the hardware itself, as there was some instances where the code did not execute properly and the board itself needed to be reset. The other issue we faced was mostly around getting used to the software and the workflow in the Eclipse IDE and the debugger. Once we understood the ways to use the tools we found our workflow sped up considerably, as we were able to check step by step and find bugs at the source. The last issue we had was with the syntax of the code, but that was solved quickly by reading over documentation and with the help of the TAs. Overall the lab went smoothly and has indeed succeeded at the goals of improving our familiarity and skill with the Netburner ColdFire system, Assembly code and Pair Programming practices.
